Q: Algorithm Efficiency on Large Input I've been doing some research on the topic of algorithms and I've come across two interesting topics: Big O complexity on large inputs (Sorting on large inputs (If I understand correctly, Big O complexity on large input is the worst case time complexity of an algorithm, while Big Omega complexity is the average case complexity. Why are we interested in Big O and not Big Omega complexity, if the average case complexity is what matters? A: There are two reasons for using big-O: It's a standard tool for judging complexity. Say you have a problem with a time complexity of $T(n)$. You can use big-O to determine if the function $f(n)$ is $O(T(n))$ or is $T(n)O(1)$ or $O(f(n))$ or $O(f(n)^2)$. It lets you measure a program's running time without knowing the value of $T(n)$ -- only its asymptotic behavior. Big Omega is less useful in practice, but is useful in some research settings. In this paper we consider the quantum measurement problem as a problem of assigning probabilities to the outcomes of an experiment. We derive the probability of a single outcome of a measurement. An important fact about this derivation is that the probabilities are independent of the state of the apparatus as far as all the information from the measured system is included in its actual state, and the dynamical evolution of the apparatus is not affected by this information. We consider the time evolution of quantum systems in a closed system and in a thermal bath. The probability of finding a system in a state after a certain time interval is derived. The expression for this probability can be evaluated in any eigenstate. We show that the result is the same for any state with the property that all the information about the system is included in the expectation value of its state. We find that the rate
